Do banks' overnight borrowing
rates lead their CDS Price?
evidence from the Eurosystem

No 1809 / June 2015

Note: This Working Paper should not be reported as representing the views of the European Central Bank (ECB). The views expressed are those of the authors and do not necessarily reflect those of the ECB

Abstract

We construct a measure of a bank's relative creditworthiness from Eurosystem's proprietary overnight loan data: the bank's "average overnight borrowing rate spread, relative to overnight rate index" (AOR). We investigate the dynamic relationship between the AOR and the credit default swap spread (CDS) of 60 banks in years 2008 - 2013. We find that in daily differences the AOR leads the CDS at least by one day. The lead is concentrated on days of market stress for banks which mainly borrow from "relationship" lender banks. Such borrower banks are typically smaller, have weak ratings, and likely reside in crisis countries. In longer differences, up to several weeks, both the AOR and the CDS have some predictive power over one another. In sum, overnight borrowing rates may provide additional early-warning indications on certain banks' deteriorating financial health over and above bank CDS spreads.

JEL codes: G01, G14, G21

Keywords: money markets, overnight borrowing rates, credit default swaps (CDS), lead-lag relationship, TARGET2, Eurosystem, early-warning indicators

Non-technical summary

The recent financial crisis has intensified the search for early-warning indicators of banks' financial distress. Money market interest rates may be one valuable source of such indicators. We contribute to the quest of early-warning indicators by forming a measure of a bank's creditworthiness: its average overnight money market borrowing rate relative to an overnight rate index (henceforth AOR). We then investigate whether this spread might provide a more timely measure of changes in the bank's creditworthiness than one of the leading market-based indicators, the bank's credit default swap (CDS) spread.

Somewhat surprisingly, we find that the AOR clearly "leads" the CDS under conditions of general market stress and especially in case of banks which are relatively more dependent on lender banks which have established a longer term lending relationship with the borrower bank. Such borrower banks are typically smaller, have weak ratings, and likely reside in crisis countries.

We use inter-bank overnight rates formed in bilateral contracts between banks who participate in the Eurosystem's TARGET2 large value payment system (Trans-European Automated Real-time Gross Settlement Express Transfer System 2). The sample includes 60 banks in years 2008 – 2013. The data is highly confidential and proprietary to the Eurosystem. The overnight market is the shortest term component of the interbank money market through which banks manage their liquidity. It is the key transmission channel for monetary policy in major central banks including the European Central Bank (ECB) and the US Federal Reserve. At the shortest maturity, the money market is an extremely liquid credit market with high frequency of observations.

Although our specification of the AOR and the CDS spread should be immune to the general changes in the liquidity conditions, we also aim to control for bank-specific effects to see whether the joint short-term dynamics of the AOR and the CDS is driven by credit risk or liquidity risk factors. The lead for the AOR over the CDS remains largely intact despite the additional controls. The information in the AOR appears to be supplementary to the information in the equity and the sovereign CDS market as well as with respect to liquidity conditions measured by the CDS bid-ask spread.

Although the results are statistically highly significant, the magnitude of the AOR effect on CDS is not large. This is in line with earlier studies on lead-lag relationships between various financial market prices.

In sum, overnight borrowing rates may provide additional early-warning indications on certain banks' deteriorating financial health over and above bank CDS spreads. Our results also imply that the AOR may provide useful information of the health of banks which do not have a traded CDS contract.

I. Introduction

In the wake of the recent financial crises, the need to understand the functioning of inter-bank money markets has grown considerably. Money market data may also be a source of early-warning indicators for future banking problems. We contribute to the quest of early-warning indicators by forming a measure of a bank's creditworthiness; its average overnight money market borrowing rate relative to an overnight rate index, and investigate whether this spread provides a more timely measure of changes in the bank's creditworthiness than the leading market-based indicator, the bank's CDS spread.

We use the proprietary data base of the Eurosystem's overnight money market which operates in the so called TARGET2 large value payment system (Trans-European Automated Real-time Gross Settlement Express Transfer System 2). The overnight market is the shortest term component of the interbank money market through which banks manage their liquidity. It is the key transmission channel for monetary policy in major central banks including the European Central Bank (ECB) and the US Federal Reserve. At the shortest maturity, the money market is an extremely liquid credit market with high frequency of observations.¹

Earlier research has already considered whether the average interest rate spread of the overnight loans taken by a bank, typically from a number of other banks, reflects the bank's creditworthiness. Furfine (2001) has shown with the Fed Funds data that the overnight borrowing rates do indeed reflect balance sheet measures of the bank's credit risk. However, to the best of our knowledge previous research has not considered how efficiently and fast these markets react to changes in credit risk. Because the average

¹ Money market transaction data are available for longer maturities as well but we will focus on the overnight data because of the far bigger market size and liquidity, and because the accuracy of identifying interbank loans out of the entire population of large value payment transactions in the data base is highest in case of the overnight loans.

overnight borrowing rate spread (henceforth AOR) of a bank is generally not publicly observable to any market participant (other than the borrower bank itself and the competent authorities, such as the Eurosystem in the current context), it is in effect an aggregated measure of the *private* signals of the banks who lend to the borrower bank concerning the borrower bank's health. We then test whether this measure provides more timely information of changes in the bank's credit risk than the bank's CDS spread.

Our choice of bank CDS spread as a benchmark is justified because CDS spread is commonly seen as the leading *public* indicator of the credit risk of both corporations and banks (see e.g. Blanco et al., 2005, Longstaff et al., 2005, and Annaert et al., 2012).² In spite of their maturity mismatch and the effect of the term structure of credit risk, new information about bank creditworthiness should on average push both the AOR and the bank CDS spread in the same direction³. Moreover, as many of the overnight interbank loans are results of longer-term lending relationships (cf. e.g. Cocco et al. 2009, Bräuning and Fecht 2012, and Abbassi et al. 2014) in which the lender may have acquired private information of the borrower, it is possible that the average bilateral loan rate contains more information of the borrower bank's health than the public CDS spread.⁴ Importantly, CDS

² There is no obvious alternative benchmark measure of bank creditworthiness based on public quotes as bond markets are generally less liquid than the CDS market. Bongaerts et al. (2011) find that CDS spreads also reflect liquidity risk but conclude that the effect is economically small although it may have grown when the global financial crisis started (their data ends in 2008).

³ The maturity of the AOR is, by definition, overnight, while we mainly use the five year CDS spread which is the most liquid CDS contract. Note that by working with spreads rather than rates we control for the term structure of risk-free interest rates.

⁴ The overnight loans market can be considered as a fragmented market whereas the CDS market is relatively more centralized. Our setting corresponds to a situation where both types of markets are open at the same time on the same asset but where prices are public knowledge only in the centralized market (the CDS market) whereas they are private knowledge in the fragmented market (overnight loans). As a result, information flows between the two markets may be asymmetric. We are not aware of theoretical papers which would exactly consider a setting of this kind although price formation in fragmented vs centralized markets has been studied e.g. by Wolinsky, 1990, and Biais, 1993. Studies on the upstairs and downstairs markets on stocks may also provide some guidance (see e.g. Booth et al., 2002). As Biais (1993, p. 175) puts it, "(a)n issue is whether inside traders can use the lack of transparency of fragmented markets to exploit their private information." Hence we may hypothesize in the current paper that the aggregate of private signals, reflected in the privately negotiated overnight loan rates, and observable as a composite only to the competent authorities, may contain more information than the corresponding public signal (the CDS price; though compared to the stock market the CDS market is more of an insider market; see e.g. Acharya and Johnson, 2007, the quotes available in Bloomberg are in principle public). On strategic behavior of informed and uninformed traders, see also O'Hara (1997; chapters 4 and 5).

spreads are in actuality based on quotes, which is another reason why the AOR may reflect changes in a bank's creditworthiness faster than the bank CDS.

Our data covers the period from the beginning of June 2008 to the end June 2013, comprising 60 banks, 1,300 business days, and around 470,000 loan transactions with average value of about 100 million EUR. These yield approximately 46,000 daily AOR observations with daily turnover of about 50,000 million EUR.

To test whether the AOR provides more timely information of a bank than its CDS, we use Granger causality tests of the lead-lag relationship between daily changes (or levels) of the AOR and the CDS, both for the panel of 60 banks as well as for individual bank time series. If the AOR were found to "Granger cause" the CDS, then we would conclude that the AOR is more informative of changes in banks creditworthiness than the CDS spread.⁵

To separate the bank-specific part of the AOR and the CDS spread from general market conditions we deduct the Euro OverNight Index Average (EONIA) from the AOR and the iTraxx-index from the CDS (we henceforth refer to the AOR and CDS in these formats unless noted otherwise). Schwarz (2014) shows that after the financial crisis liquidity risk has explained the major part of the general rise in inter-bank and sovereign interest rate spreads. Although our specification of the AOR and the CDS spread should be immune to the general changes in the liquidity conditions, we also aim to control for bank-specific effects to see whether the joint short-term dynamics of the AOR and the CDS is driven by credit risk or liquidity risk factors.

As a first test of whether the AOR and CDS are driven by the same factors in the long-run we study their co-integration relationship. In contrast to corporate bonds and CDSs with

⁵ We also investigate how the lead-lag relationship is affected if longer differences of the AOR and the CDS, up to several weeks, is used.

matched maturities in Blanco et al. (2005), we find no compelling evidence of co-integration between the AOR and the CDS. However, the long-run average AOR and CDS are clearly correlated (see Figure 2), and the daily cross-sectional correlation between the AOR and the CDS varies greatly (see Figure 3) suggesting that at least near co-integration might exist in certain subperiods, perhaps depending on the market conditions. During tranquil times, the overnight lenders to a bank may be less concerned about sudden changes in the borrower bank's creditworthiness. Because of the extremely short maturity (one day or even less) of the loan, other factors such as bank size, relationship with the lender, and general liquidity conditions may be more important determinants of the AORs.⁶ But because overnight loans are typically quite large and uncollateralized, the AOR may become more informative of the borrower's credit risk in times of stress when lender banks become concerned of the asset quality and liability structure of the borrower bank.⁷ This would be consistent with what we find: the daily cross-sectional correlation between the AOR and the CDS increases during the Lehman episode and again in the run-up to and during the so called Eurocrisis that started accelerating in the Spring of 2010 (see Figure 3). This may be further understood with the theory of Dang, Gorton and Holmström (2012): according to them the price of a money-like debt instrument (the AOR in our case) becomes sensitive to the issuing institution's asset quality only when sufficiently bad public news concerning the asset quality inflict private information acquisition among the investors (the lender banks in our case). Hence, it is understandable that in the depths of the Eurocrisis even the extremely short-maturity overnight interbank money market loans became increasingly sensitive to borrowing banks' credit risk.

⁶ Covitz and Downing (2007) provide evidence from commercial paper spreads of non-financial companies that credit risk dominates liquidity risk even at very short maturities.

⁷ Afonso, Kovner and Schaar (2011) using US overnight money market data find that "the day after Lehman Brothers' bankruptcy, loan terms become more sensitive to borrower characteristics".

Our main empirical finding is that the AOR leads the CDS. The lead is at least one day long in a panel regression setting and quite robust with respect to other factors such as equity which has previously been found to lead the CDS (see Acharya et al., 2007). Conversely, no significant lead relationship is detected for the CDS over the AOR. When the lead for AOR over CDS is estimated over the entire data period, the relationship is significant but not very strong. However, the strength of the lead relationship varies strongly in time according to rolling panel estimation, reaching its peak in mid-2012 during the Euro's "existential crisis".⁸ This together with bank-specific results which show considerable heterogeneity in the lead coefficient suggests that the AOR's lead over CDS is not a general phenomenon but conditional on the amount of market stress and bank characteristics.

Therefore we also allow for separate lead-lag coefficients (with the help of a dummy variable) for banks with different characteristics, differentiated on the basis of relative weakness (measured by, e.g., the bank's credit rating), the bank's home country being a crisis country, the bank being mainly a relationship borrower⁹, the size of the bank, or the liquidity of the bank's CDS. We find that the lead for AOR over the CDS is stronger for relatively weaker banks, for banks residing in crisis countries, for relatively relationship-intensive borrowers, for smaller banks, and for banks with a less liquid CDS market. In a number of model specifications the base coefficient becomes insignificant which suggests that the AOR's lead over CDS is indeed not a general but strongly conditional property.

The first two of the above results clearly suggest that the lead for the AOR over CDS is stronger when a bank's overnight loans' information sensitivity is relatively high; that is,

⁸ The gradual end of this episode is marked by the ECB president Mario Draghi's famous "whatever it takes" speech on July 26 2012 and the subsequent announcements by the ECB Governing Council later that year concerning its Outright Monetary Transactions (OMT) program.

⁹ We use the measure suggested by Cocco et al. (2009) and discuss below the details of how that is calculated on the basis of the proprietary Eurosystem data.

for relatively weak banks, and for banks residing in crisis countries. These banks are less likely to get support from their crisis stricken governments, may have domestic sovereign debt holdings which have deteriorated in value, and suffer from an overall decline in their asset quality resulting from their depressed domestic economies. Regarding the stronger AOR lead result for banks who are relatively relationship-intensive borrowers, it can be argued that, first of all, relationships become relatively more important in times of market stress when the information sensitivity of the overnight loans increases. Relationship lenders are likely to be best positioned to acquire further information in a stress situation while less informed lenders may reduce or stop their lending. This view is supported by the fact that correlation between the iTraxx-index, measuring the level of market stress, and the average relationship-borrowing intensity of banks is 44% in our sample period¹⁰. Secondly, when the share of the allegedly better informed relationship lenders of all lenders to the bank is high, the AOR should be more informative of the bank's health. This would imply the stronger lead for such banks' AOR over their CDS, which we find. Finally, both for smaller banks and banks with less liquid CDS, which also have a large overlap, the AOR exhibits a stronger lead. This suggests that for smaller banks the overnight lenders' may be mainly relationship lenders (cf. Cocco et al. 2009) whose better private information may strengthen the lead for AOR over CDS. Also, if CDS market itself is less well functional (as proxied by the bid-ask spread) the lead of the AOR may increase.

With a similar approach, we categorize the business days corresponding to various crisis periods or alternatively according to the stress of the financial markets, proxied by iTraxx CDS index. We find that during the sovereign debt crisis and generally during times of relatively high market stress, the lead of AOR over CDS is stronger. Finally, conditioning

¹⁰ When calculating the correlation we control for the potential effect of the ECB's July 2012 operations on the iTraxx index.

the lead relationship on the interactions between the different classifications of banks, we find that the lead for the AOR over the CDS is strongest and most robust on days of market stress for banks which are relatively relationship-intensive borrowers. We find evidence that such banks are typically smaller, have weak ratings, and likely reside in crisis countries.

Why is it that the lead for AOR over CDS is stronger when the information sensitivity of a bank's overnight loans is relatively strong and when the bank mainly borrows from relationship lenders? The reason may be that as lenders' incentives to engage in private information acquisition about the bank's true asset quality increase, the role of private information incorporated in the AOR strengthens so that its informational advantage relatively to the CDS price, measured by the lead coefficient, increases.¹¹

In sum, the contribution of this paper is to show that a bank's average overnight borrowing rate spread leads the bank's CDS spread for banks whose overnight loans are relatively information sensitive in the sense of, e.g., Dang et al. (2012). This result has the following implications. First, it suggests that by using the private overnight interbank-loan interest rate data, the Eurosystem authorities may be able to extract more timely and complementary information concerning banks' current condition over and above the leading public market signals; banks' CDS prices. The informational contribution of the AOR increases during market stress, and is accompanied with a relatively stronger presence of relationship lenders in the overnight market. The economic significance of the informational contribution of the AOR is not very large, but the results also imply that the AOR can be a useful indicator of bank health for banks without traded CDS contracts.

¹¹ We also attempt to control for whether the lead might be related to liquidity risk factors rather than credit risk factors. However, when the information sensitivity of debt increases as its credit risk increases, its liquidity may decline as problems of asymmetric information may arise at the same time; see e.g. Holmström (2014). Hence there may be a fundamental link between the two risk components so that disentangling them might be difficult.

Second, our results may be among the first to provide support to a hypothesis that an aggregate of private signals concerning an asset's value may be more informative than the price of the same asset, formed in a simultaneous public market. The situation may be seen as somewhat analogous to social theories whereby the average of independent estimates (comparable to the AOR in our case) is found to be more accurate than individual or even consensus estimates (which may be compared with the CDS market price in our case); see Asch (1955) and Surowiecki (2004).

The paper is organized as follows. Section II A shortly describes the European interbank market followed by an overview of variables in Section II B. Section III A covers time series properties of the data and the testing set-up. The main results and various robustness checks are presented in Section III B. The final Section IV concludes.

II. The data

A. Structure of the European interbank market

We start the description of our data by explaining the basic infrastructure of the Euro area interbank money market. The Euro area monetary policy operations as well as the majority of transactions in the Euro area interbank market are settled in the so called TARGET2 system which is the large value payment system of the Eurosystem.¹² Access to TARGET2 is granted primarily to credit institutions, national central banks, and treasury departments of European Union member states, which are active in the money market, while most other financial firms and non-financials have no access (see Heijmans et al., 2010). Money market transactions are a subset of bank-to-bank large value payments. In 2012,

¹² The Eurosystem is formed by the national central banks of the European countries belonging to the European Monetary Union (having euro as their common currency) and the European Central Bank (ECB). In addition, a number of non-euro European countries, six in 2010, were also connected to TARGET2.

TARGET2 had a 92% market share in value terms of all large value payments in euro.¹³ Payments are settled in central bank money with immediate finality (i.e., in real time). TARGET2 and Fedwire Funds for the US dollar are the two largest real-time gross settlement systems in the world.¹⁴ In the current paper, our analysis is based on access to the proprietary TARGET2 database of the Eurosystem.

B. Panel and variables

60 banks panel

Arciero et. al. (2013) have provided the Eurosystem with a database of euro area money market transactions. The money market loans are identified from all TARGET2 transactions by an improved version of the algorithm originally suggested by Furfine (2001). The Arciero et. al. algorithm is able to identify loan transactions with fair accuracy up to 3 month maturities, while the reliability is especially good for the overnight segment considered in this article. We use a further improved version of the Arciero et. al. (2013) algorithm, which uses the additional information on the originator and beneficiary fields of the transactions¹⁵. As discussed in Armantier and Copeland (2012), taking into account the originator and beneficiary fields is important for the quality of the algorithm because of the possibility for correspondent banking. The time period of the dataset considered is from the beginning of June 2008 when the TARGET2 was fully operational to the end of June 2013.

The raw money market data is a list of pairs of transactions (the loan issue and refund amounts), while the related transaction details contain the information of the borrower and

¹³ See European Central Bank (2013). Another, privately owned euro payment system for banks operating in the European Union is called EURO1.

¹⁴ See TARGET2 Newsletter, I Issue, number 3, October 2010.

¹⁵ We thank Arciero et. al. for providing this update.

lender identity, the loan issue and payback values from which the loan interest rate can be calculated, and the time that the loan was issued and later paid back. The borrower and the lender are identified with Business Identifier Codes (BICs). As one banking group may consist of several entities with their own BICs, we use information from the Swift BIC directory in order to consolidate the different entities under the common banking group. At this point any loan transactions that have taken place within banking groups are discarded and we are left with 799,276 loan transactions and 1,177 banks. For all banks that are active in the money market during the time period, the corresponding Bloomberg CDS and stock ticker is matched if possible. Finally, those transactions in which the borrower bank has insufficient CDS data are left out so that a dataset with 60 borrower banks (domiciled in 19 different countries), 984 lender banks and 470,160 loan transactions is obtained. In 23% of the loans the lender is also within the 60 banks. Overall this translates into 53,987 daily observations.

Because banks with low creditworthiness may face rationing in the overnight loans market especially during times of market stress, there is a sample selection bias in the sense that more creditworthy banks are overrepresented in the data. This bias leads to weaker overall results because, as we find, the sensitivity of the overnight rates is lower for more creditworthy banks.

Table 1 includes descriptive statistics for the 60 bank panel. For the time period mid-2008 to mid-2012 there were around 12,000 observations per year. After mid-2012 the overnight money market activity decreased due to change in the monetary policy rates and did not recover until the end of the data period. The decrease in money market activity is also accompanied with a change towards more concentrated markets with fewer counterparties, as measured by the bank relationship variables (see below for their precise definitions).

Average Overnight Rate spread

For each business day a bank may have borrowed from several lenders so we aggregate the daily rate from the multiple borrowings.¹⁶ The loan issues generally take place between 7 am and 6 pm Central European Time (CET) during the TARGET2 Day Trade Phase. Rates in transactions towards the end of the day are likely more informative so the time stamp could be used as a weight in the aggregation.¹⁷ The informativeness of a single transaction rate could also depend on the value of the loans or of the intensity of the borrower-lender relationship. One could imagine giving accordingly more weight to lenders that have close relationship with the bank (measured by past lending volume) or to loans that are of higher value. However, we found that different weighing schemes have only minor effect on the results so we simply use uniform weights in the daily rate aggregation per bank.

To facilitate a comparison with the CDS price, which is a spread in itself, the average overnight rates need to be turned into average overnight rate spreads using suitable loan rate index. We find Euro OverNight Index Average (EONIA) the most natural candidate since it helps to account for general conditions in the euro money markets (e.g. the effects of policy rate changes, liquidity operations, and seasonal effects due to maintenance periods). Since the EONIA itself is not a risk-free rate¹⁸, the CDS prices need to be transformed correspondingly (see the next few subsections). Henceforth, we call the spread between the average overnight rate and EONIA simply AOR.

¹⁶ In the case that a bank has not borrowed at all overnight on a given day, this (spread value) will be treated as a missing observation in our unbalanced panel regressions.

¹⁷ The correlation between "early" (before 12:00 CET) and "late" (after 12:00 CET) loan rate is 0.67, while the latter has slightly higher correlation with the CDS price (0.50 vs. 0.42). Also while both significant alone, the "late" rate has a larger (Granger) causal impact on the next day's CDS price.

¹⁸ The credit risk of EONIA is the value weighted credit risk of those who borrow from the EONIA panel banks.

$$AOR_{B,t} = \frac{1}{N_{B,t}} \sum_i R_{i,t}^{L_{i,t} \rightarrow B} - EONIA_t . \quad (1)$$

Here B refers to a borrower bank, $L_{i,t}$ is a lender bank for the i th loan in day t and $R_{i,t}^{L_{i,t} \rightarrow B}$ is the rate of the corresponding loan while there are total $N_{B,t}$ loans to bank B on day t (see also Figure 4 for illustration of the calculation of the AOR).

Figure 1 illustrates the variation of AOR and CDS across observations. Because of the differing maturity of AOR (1 night, EONIA deducted) and CDS (5 years, iTraxx deducted) the points do not fall around a straight line. Because the term structure of credit risk varies from observation to observation, one AOR is mapped to many different CDS values at different times. However, as shown in Figure 2, as we average over the different observations of each bank, the points fall around a curved line whose dimensions reflect the average term structure of credit risk, which most of the time was upward sloping during the data period. Hence small changes in AOR are accompanied with larger changes in CDS. Note that there is additionally a nonlinear effect whereby the changes in the AOR yield increasingly larger changes in CDS as AOR increases.

Euro OverNight Index Average (EONIA)

The EONIA rate is calculated each day by the European Central Bank (ECB) based on the actual overnight loan transactions reported by a set of contributing –banks. The overnight loans include all the overnight loans granted by the contributing banks before the close of TARGET2 at 6 pm CET and are weighted according to their value. At the time of writing, the EONIA panel consists of 34 contributing banks many of which (though not all) are included in our 60 banks panel. The correlation between EONIA and the mean unweighted rate of the 60 banks is very high (0.998) and the results presented later are robust towards selecting either EONIA or the mean rate as the reference rate in AOR.

Credit-Default-Swap (CDS) spread with respect to iTraxx

Banks' CDS price data are obtained from Bloomberg and based on quotes rather than actual trades. We use the last price field, which corresponds to the mid-price at the end of trading. Because of time zone differences the end of trading time may vary across the banks. Typically the trades take place in London and thus the price is quoted an hour or so later than the time at which the TARGET2 Day Trade Phase ends (most of the overnight loans also take place well before closing). The CDS quote is hence somewhat later than the average money market transaction, which gives the CDS a small informational advantage¹⁹. We only consider the CDS of the most liquid maturity, the 5 years. To facilitate a comparison with the AOR marginal, we need to deduct the general market risk present also in EONIA from the CDS. This is achieved by deducting the iTraxx Europe Financials CDS index (varying composition) from the bank CDS. For brevity, in Part III we call this spread between the bank CDS and the iTraxx CDS index merely CDS. An exception is the Sovereign CDS used as a control in Section III.C, which is employed as such.

Markit iTraxx Europe Senior Financial subindex

The iTraxx Europe index also known as "The Main" is composed of the 125 most liquid CDS' of European entities. We use its sectoral subindex for financials, which consists of 25 equally weighted names most of which are direct participants in TARGET2. Similar to EONIA, the iTraxx index has a high correlation (0.93) with the mean CDS price in our 60 banks panel, and the results are robust against if the panel means are used instead of the indices.

¹⁹ This may slightly work against the likelihood of rejecting our key null hypothesis of interest that the AOR does not lead the CDS.

Credit-Default-Swap (CDS) bid-ask spread

The CDS bid-ask spread is used to proxy the liquidity of the CDS. Because of the data availability issues we use two approaches for the bid-ask spreads. In the first approach we obtain the daily bid and ask CDS price data from Bloomberg for 57 of the 60 banks (for three of the banks the data was unavailable) and calculate the bid-ask spread for each day. The bid-ask spread has a strong correlation (0.84) with the CDS price itself. In a second approach, we obtain a snapshot of the real time bid-ask spread on a tranquil day in 2013, which is available to all 60 banks. Apart from small numerical differences the regression results are independent of, which CDS bid-ask spread dataset is used. We therefore prefer to use the snapshot bid-ask spread dataset, which allows to keep all 60 banks in the sample.

Borrower Preference Index (BPI)

Similar to lending relationships between banks and corporates, there exist lending relationships between banks in the overnight loan market. We measure the intensity of an interbank relationship by calculating how large a share that relationship contributes to borrower's total borrowing during a period of time. Following Cocco et al. (2009) we define the Borrower Preference Index (BPI) as the ratio of funds, F , that bank B has borrowed from bank L over a given time period Q_t , denoted $F_{Q_t}^{L \rightarrow B}$, as a fraction of the total amount of funds that B has borrowed in the market in that same period denoted $F_{Q_t}^{any \rightarrow B}$

$$BPI_{L,B,t} = \frac{F_{Q_t}^{L \rightarrow B}}{F_{Q_t}^{any \rightarrow B}} \cdot \quad (3)$$

For each business day, we take the time period to be the last 62 business days including that day, t , which corresponds to one quarter.

To obtain a single number that quantifies the reliance on relationships of a given borrower on a given day, we further average over the different borrowings of that bank on that day:

$$BPI_{B,t} = \frac{1}{N_{B,t}} \sum_i BPI_{L_{i,t},B,t} . \quad (4)$$

As in Eq. (1), $L_{i,t}$ is a lender bank for the i th loan in day t while it is entirely possible to have several borrowings from the same lender bank. In the sum over loans it is natural to use the same weights as in the AOR i.e. in our case uniform weights. Note that both of the BPIs defined above attain a value between 0 and 1. Figure 5 shows the mean BPI and iTraxx CDS Index for 60 bank panel. The larger the value of $BPI_{L,B,t}$, the stronger the relationship. Similarly larger $BPI_{B,t}$ indicates on average larger reliance on relationships. Since averaging the BPI as above loses some amount of information and potentially lessens the relevance of BPI, it was checked that linear regressions of AOR on CDS and BPI yield similar enough coefficients irrespective of whether the bank relationships in BPI and AOR are taken explicitly into account or averaged over. The finding was that for our panel, in both cases the BPI is informative and highly significant while the coefficient of $BPI_{B,t}$ is some 35 % smaller than the coefficient of $BPI_{L,B,t}$. Henceforth, we refer always to the $BPI_{B,t}$ when discussing of BPI.

Herfindahl-Hirschman Index (HHI)

As an alternative proxy for the market structure and relationships we develop an application of the Herfindahl-Hirschman Index (HHI) to measure how concentrated the borrowing activities of a given bank are on a given day. HHI is the total of squared daily market shares of each lender bank in the market of "all lending to borrower bank B ". If $F_t^{L \rightarrow B}$ is the amount funds bank B borrowed from bank L on day t , and $F_t^{any \rightarrow B}$ is the amount funds bank B borrowed in total on day t , the HHI is written as

$$HHI_{B,t} = \sum_L \left(\frac{F_t^{L \rightarrow B}}{F_t^{any \rightarrow B}} \right)^2 . \quad (5)$$

Similar to BPI, the HHI index takes a value between 0 and 1. Generally when the HHI is larger, the market is more concentrated.²⁰ Figure 5 shows the mean HHI along with mean BPI and iTraxx CDS Index. During times of financial market stress (as proxied by the iTraxx index) the average BPI and HHI show also heightened values indicating more concentrated credit lines and more reliance on relationship lending.

Credit rating

As a credit rating proxy, we use the Standard & Poor's Long Term Foreign Currency Issuer Credit Ratings. Following Covitz and Downing (2007), the ratings are converted to numerical values by assigning a number to each credit rating such that the set of credit ratings AAA, AA+, AA, AA-, A+, A, A-, BBB+, BBB, BBB-, BB+, BB, BB-, B+, B, B-, , CCC+, CCC, CCC-, CC, C, and D maps to integers from 0 through 21. Higher number corresponds to higher credit risk. We have considered taking into account negative/positive outlook by adding/subtracting 0.5 but this seem not affect the leading decimals of the regression results.

Stock price

Stock price movements have been found to lead the CDS prices for investment grade entities while the CDS prices may lead stocks in the high-yield credit market (see e.g. Acharya et al. 2007, Fung et al. 2008, Marsh and Wagner 2011, Giannikos et al. 2013), so bank stock price is therefore a natural factor to control for. The prices are quoted at the end-of-day for the particular stock exchange. Later we will find that both the AOR and

²⁰ U.S. Department of Justice and Federal Trade Commission (2010) classify HHI<0.15 as unconcentrated market, 0.15<HHI<0.25 as moderately concentrated market, and HHI>0.25 as highly concentrated market.

stock prices lead the CDS prices with the stock price movements having a somewhat stronger effect.

Balance sheet variables

We obtain a set of balance sheet variables from Bloomberg as additional controls: 1) Total debt to total assets, 2) Total debt to common equity, 3) short-term (ST) debt to total liabilities, 4) long-term (LT) debt to total liabilities and 5) (logarithm of) total assets (or equivalently total liabilities). In 1 and 2 total debt includes ST borrowings, LT borrowing and securities sold with repo agreements and excludes total deposits and liabilities that do not bear explicit interest. ST debt includes the ST borrowings, securities sold with repo agreements and other ST liabilities (such as those that do not bear interest). LT debt goes similarly apart from the repos, which were already counted to ST liabilities. Total liabilities is ST and LT debt + total deposits.

TARGET2 liquidity

As a response to the crisis, the ECB provided large amounts of liquidity to the banking system. ECB's Statistical Data Warehouse offers public data on daily liquidity conditions. We define the liquidity to be the amount of central bank money in the current account plus in the deposit facility.

Other control variables from the TARGET2 money market data

The TARGET2 money market data offers a multitude of potentially interesting controls. First, we have the following bank-specific controls with daily frequency: (logarithm of) amount borrowed, (logarithm of) number of lenders, lending rate (spread to EONIA), and standard deviation of borrowing rates. Second, we have the following additional controls with daily frequency: (logarithm of) total overnight market volume, (logarithm of) total

lender count, (logarithm of) total borrower count, standard deviation of all overnight market rates. As the credit risk is the leading cause of variation in overnight rates, the market wide standard deviation of overnight rates gives an idea on how the credit risk is distributed across the different banks. For the standard deviation variables we have also used percentile differences as alternative dispersion measures (and found the results unchanged).

Euro General Collateral Repo Market Rate (EUREPO)

EONIA is based on realized uncollateralized loans and contains credit risk. The risk premium in EONIA can be proxied by observing the spread to the less risky Euro Repo Market Rate (EUREPO), which is the rate at which at 11.00 am Brussels time, one bank offers funds in euro to another bank against European government guaranteed bonds and bills as collateral.

Figure 6 shows together the EUREPO-EONIA spread, the standard deviation of overnight rates in the money market and the iTraxx index. The high correlation between the three confirm that both the short-term and long-term credit risk has been relevant during the past years, and also that the risks have been unevenly distributed across banks.

III. Empirical analysis

A. Testing for co-integration between the AOR and the CDS

From purely theoretical viewpoint it is difficult to see why interest rates or interest rate spreads would be non-stationary. However, in finite time-series samples such evidence is often found. Hence, we also start our empirical analysis by testing for the stationarity of and co-integration between the bank-specific time series of the AOR (spread) and the CDS (spread); cf. e.g. Blanco et al. (2005). Obviously, the AOR and the CDS could be closely

related if they reflect the same fundamentals concerning a bank's creditworthiness, unless the AOR is relatively information insensitive in normal times due to its overnight maturity. Hence, it is possible that a co-integration relationship between the AOR and the CDS exists only during crisis periods when the AOR's information sensitivity increases.

The Augmented Dickey-Fuller (ADF) test, when performed separately for each bank, detects no unit roots for the AORs of the sample banks. In contrast, a unit root in the CDS is detected for around half of the banks. Unit root tests in the panel setting give consistent results. Despite the failure of the ADF test to detect unit roots for the AORs, the Johansen co-integration test finds one co-integrating vector between the AOR and the CDS for around one third of the sample banks. These test results appear to be rather robust to lag order selection. In sum, because the evidence for non-stationarity and co-integration is not compelling, we use the standard Vector Autoregressive model in the subsequent analyses. To control the robustness of our results, we will estimate the lead-lag model for the AOR and the CDS both in levels and differences.

B. The lead-lag relationship between the AOR and the CDS

The test for our main hypothesis that the AOR may lead the CDS is conducted in the standard VAR framework, using the Granger causality setup. We focus on a panel VAR but provide also bank-specific time series results. When controlling for various bank characteristics, we use interactions between the lead-lag relationship of the AOR over the CDS and various dummy variables to test whether the lead relationship is stronger for certain bank types and time periods, consistent with the information sensitivity hypothesis. Our empirical hypotheses are summarized in the following list. Hypothesis $H2(v)$ that the lead for the AOR over the CDS is stronger for banks whose CDS is relatively illiquid is added to hypotheses $H2(i)-(iv)$ which are directly motivated by the theory of Dang et al.

(2012). Hypothesis $H2(v)$ could be justified by the findings of Blanco et al. (2005) who argue that the CDS leads the corresponding bond price partly due to better liquidity. By the same logic we could postulate that if the AOR were to lead the CDS, the lead should be stronger if the CDS market is relatively illiquid.

Hypothesis 1: The AOR leads the CDS in the sense that it “Granger causes” the CDS (henceforth H1)

Hypothesis 2: The AOR’s lead over the CDS is stronger (henceforth H2)

- i) during financial market stress (crisis periods)*
- ii) for relatively weaker banks*
- iii) for banks in countries with a sovereign debt crisis*
- iv) for banks which are relatively more dependent on relationship lenders*
- v) for banks whose CDS price is relatively illiquid*

The VAR model in the panel setting takes the form:

$$y_t^{(b)} = a_{0,b,t} + \sum_{i=1}^k A_i y_{t-i}^{(b)} + e_t^{(b)} \text{ for each business day } t \text{ and bank } b. \quad (6)$$

Here matrix A_j contains the panel regression coefficients shared by all banks and obtained by ordinary least squares (OLS). Vector $a_{0,b,t}$ denotes the constant term that may also represent fixed time or cross-section (bank) effect. By the fixed bank effects we control the specific features of banks for which we do not have data such as credit ratings. Elements of vector $y_t^{(b)}$ are the daily change in the AOR for bank b , the daily change in the CDS for bank b , and the control variables.

In order to fix the lag length of the VAR process we use the conventional information criteria. The Schwarz Bayesian information criterion (SBIC) has a minimum at 5 lags for

the CDS. This corresponds to one week since only business days are included. In the case of the AOR, no clear minimum was found. In reporting our main results, we use one lag for both the AOR and the CDS, but consider also 5 lags to ensure robustness of results.

Table 2 reports results for the basic panel VAR, both in levels (panel a) and differences (panel b), in which we include only the AOR and the CDS. Panel c) further tests if our main result is due to system wide or idiosyncratic shocks.²¹ The results clearly indicate that there is a lead only for the AOR over the CDS, but not the other way around. Especially from the difference form (panel b) we readily see that the lead is positive. Equations (1) and (2) in panel c) of Table 2 confirm that the results hold even if the indices are not explicitly subtracted. Moreover, as the EONIA and iTraxx do not lead one another, we infer that the lead is due to idiosyncratic rather than system-wide shocks in the credit risk. These results are consistent with hypothesis *H1*. Note that the equations where the AOR is the dependent variable exhibit strong negative autocorrelation which apparently captures the occasional peaks and reversals in the AOR series.²² A robust estimation of the Table 2 regressions shows, however, that the results are not driven by outliers. Below we will work with and extend the difference form of the model in Table 2 because that lends itself more readily for interpreting the sign and size of the lead coefficient.

The results in Table 2 (panels a-d) suggest that AOR leads CDS at least by one day. In addition, we also investigated the dynamic relationship between longer differences of the AOR and the CDS. To this end, we generalize the specification in Equation 6 as

²¹ Due to the sample selection bias that arises from credit rationing that less creditworthy banks face during times of market stress, the results are probably much weaker than without this bias, as explained earlier.

²² There are a number of reasons related to the functioning of the overnight money market, which may cause these peaks and immediate reversals. In particular, until 13 December 2011 the Eurosystem used one-day liquidity absorbing fine-tuning operations related to changes of the reserve maintenance period, which typically had the effect that the overnight rates temporarily rose towards the monetary policy steering rate. Moreover, the peaks are not always uniformly distributed across banks so that after the EONIA is subtracted, occasional peaks remain.

$$\Delta_h y_t^{(b)} = a_0 + A_h \Delta_h y_{t-h}^{(b)} + e_t^{(b)} \text{ for each business day } t \text{ and bank } b, \quad (7)$$

where the lag is now specified to horizon length and we have explicitly written the differences $\Delta_h y_t = y_t - y_{t-h}$. Figure 7 shows the lead coefficient of AOR and its adjusted²³ standard error in the CDS-equation for different horizon lengths, starting from our base case of the one-day difference up to a 60-day difference. Interestingly, around one-month differences the lead coefficients are quite high and many of them are significant even when we use standard deviations which control for the overlapping observations. However, with the longer differences we find a symmetric response to the opposite direction indicating bidirectional Granger causality between these variables as shown by Figure 8. Table 2, panel e) reports the lead-lag results in both directions using the 36-day difference of the AOR and the CDS series, for which the AOR's lead over the CDS reaches its highest coefficient (see Figure 7). The lead-lag relationship becomes less ambiguous when we introduce either fixed time or bank effects or both at the same time. Then Granger causality seems to run only from the AOR to CDS and not vice versa.

It is more challenging to interpret these findings with longer differences. It is possible that longer horizon price changes in one market contain cumulative information of banks' performance, which helps to predict price development in the other market. In particular, it is plausible that the price of the CDS contract, which has a five-year maturity, may contain longer term information which helps predict longer term changes in the overnight borrowing rates of a bank. In general, these longer term lead results which go in both directions are also consistent with the view that the two markets are not always perfectly integrated so that longer term information transitions between them may take place.

²³ The standard errors are adjusted for overlapping observations using the method of Bayley and Hammersley (1946), see also Garrett and Petrie (1981) and Valkanov (2001).

Table 3 (panel A) extends the model of Table 2 by considering a large set of control variables, added to the basic model one at a time. The lead for the AOR over the CDS stays statistically very significant in all cases although a number of the control variables obtain simultaneously significant coefficients. For instance, consistent with Acharya et al. (2007) we find that the lagged log difference of bank's stock price negatively predicts the bank CDS price change. Also the lagged change of the sovereign CDS price of the country in which the bank resides predicts the change in the bank CDS price. Furthermore, the CDS bid-ask spread obtains a positive sign, indicating that worsening liquidity may partly explain changes in the CDS spread, but the effect is not statistically significant. The size of the AOR's lead remains practically unchanged. In sum, because the coefficient of AOR remains largely intact despite the additional controls, the information in the AOR appears to be supplementary to the information in the equity and the sovereign CDS market as well as with respect to liquidity conditions measured by the CDS bid-ask spread. As already discussed above, it may be difficult to determine how much the lead is related to credit risk and how much to liquidity risk factors as the two may be fundamentally interwoven.

In Table 4 we report the basic VAR results (without control variables) for individual banks.²⁴ The results indicate large variation of the lead-lag relationship between the AOR and the CDS among individual banks. Only a relatively small subset of banks (7 out of 60) exhibits a statistically significant coefficient with 5 % significance level on the lead for the AOR over the CDS. Each of the significant coefficients is positive, and more than two thirds of all coefficients are positive. In the other direction, the lead for the CDS over the AOR, there is also a small subset of banks (6 out of 60) with statistically significant coefficients but with occurrences of both signs of the coefficients. Overall, the

²⁴ Note that because of the high confidentiality of the individual bank data, individual bank results are numbered in a random order with no link to actual bank identities or bank attributes.

heterogeneity of the bank-specific results suggests that the positive lead for the AOR over the CDS which we find in the panel setting may not be a general phenomenon but perhaps concentrated in certain time periods (allegedly market stress) and certain banks (banks' whose overnight debt is relatively information sensitive). Therefore we next reconsider the panel VAR results by conditioning the strength of the lead on market conditions and bank characteristics.

Table 5 extends the basic results of Table 2 by adding conditioning variables. The idea in Table 5 equations is that we condition the lead for the AOR over the CDS (henceforth "the lead") on a number of dummy variables which proxy for the factors listed in hypotheses *H2: i) – v)* above plus some additional controls.

Concerning hypothesis *H1*, equations in Table 5 show that the base coefficient of the lead is positive in all except for two cases (regressions A(6) and D(1)), the coefficient is statistically insignificant in about half of the regression (i.e., the hypothesis that it is zero cannot be rejected in these cases), depending on the specific conditioning dummy-variables included in the various equations. The conclusion from these results is that the lead is not a general phenomenon, or is at least quite weak, but may rather be specific to certain banks and time periods. We next turn to evidence on this.

Consistent with hypothesis *H2(i)*, Panel A of Table 5 provides evidence that the lead for AOR over the CDS depends on general market conditions and is stronger during crisis periods, especially during the sovereign debt crisis in Europe (see regression A(3)). The crisis effect on the lead is best captured by the dummy variable which indicates days when the iTraxx index has been above its sample time-series median (regression A(4)). The TARGET2 liquidity measure, appearing in equations A(5)-A(6), and reflecting the ECB's liquidity support measures during crisis periods, also indicates periods of strengthened

lead. Note that according to regression A(2) the lead is quite weak during the period after Lehman's bankruptcy but before the escalation of the sovereign debt crisis in 2010. This is consistent with that soon after Lehman the EU governments essentially guaranteed their banking sectors. However, the sovereign debt crisis questioned the solidity of these guarantees in many countries. Our results show that the information sensitivity of overnight loans changed accordingly from quite insensitive to sensitive: the effective size of the AOR's lead coefficient in regression A(2) is 0.015 while in regression A(3) it is 0.065, more than a quadruple, and statistically very significant.

In panel B of Table 5, the lead is conditioned on alternative proxies of bank quality as well as on the bank domicile, hence testing for hypotheses $H2(ii)$ – (iii) . We use three alternative indicators to proxy for (relative) bank quality on a daily basis: 1) if a bank's daily CDS is above the same day's cross-sectional median CDS of all sample banks, 2) if a bank's daily AOR is above the same day's cross-sectional median AOR of all sample banks, and 3) if a bank's public credit rating (measured on the 21-notch numbered scale) is below (numerically above) the daily cross-sectional median rating of all sample banks. The first three of these quality proxies supports hypothesis $H2(ii)$ that the lead is stronger for weaker banks, being consistent with the view that weaker quality increases bank debt's information sensitivity; see equations B(1)–B(3), respectively. Also bank domicile in a crisis country strengthens the lead (regression B(4)), which is consistent with hypothesis $H2(iii)$.²⁵ However, when the alternative bank quality measures appear jointly (equations B(5) and B(6)), only the rating-based relative quality indicator remains statistically significant.

²⁵ A crisis country is defined as being one of the so called GIIPS countries; Greece, Ireland, Italy, Portugal or Spain.

Equations in panel C of Table 5 test hypotheses $H2(iv)-(v)$. Regressions C(1) and C(2) indicate that the statistically significant lead is concentrated on days on which a bank borrows mainly from its relationship lenders, measured by the BPI index, and the borrowing is relatively concentrated, as measured by the HHI index. Regressions C(5)–(6) further confirm that the relationship indices (BPI and HHI) as a conditioning variable are also quite robust. Hypothesis $H2(v)$ that the lead is stronger for banks with a less liquid CDS gets supported by regression C(4) but the result is not robust when all variables in panel C are included (regression C(5)). Bank size could also be a proxy for a bank’s reliance on relationship lenders, but also for bank quality or the illiquidity of its CDS. Regression C(3) shows that smaller banks exhibit a stronger lead and that the effect is not entirely related to relationship lending as bank size as a conditioning variable maintains its significance against the BPI index (regression C(6)).

In panel D of Table 5 we consider together all variables in panels B and C and the most promising combinations of them. The only conditioning dummy-variables which are statistically significant when all these variables are present are the BPI and HHI indices (regression D(1)). The robustness is further confirmed in equations D(2)–(5) where the BPI index is controlled against other selected variables one by one. Similar robustness checks for the HHI index (not shown) yield much the same results.

In panel E of Table 5 we add double interaction terms such that we simultaneously condition the strength of the lead on periods of market stress, proxied for by the iTraxx index from panel A, and on each of the most promising conditioning variables detected in panels B and C. Equations E(2)–E(5) show that the effect of each of the conditioning variables which performed relatively well in the previous regressions gets further amplified on days of market stress. In fact, in each case the effective lead coefficient is essentially zero during “normal” times. Note that the lead coefficient conditioned on one

of the double interaction terms is almost identical throughout all equations E(2)–E(5). This hints that the different conditioning variables together with the market stress indicator may proxy for the same fundamental factors. Equations E(1) and (6) show that when the different double interaction terms appear jointly, the two statistically significant conditioning double interaction terms are the BPI index together with the market stress indicator and the HHI index alone without the market stress indicator (the latter being somewhat less significant). Moreover, by comparing say regression A(4) with E(4) we see that conditioning on the BPI index indeed increases the lead coefficient and hence has an independent effect over and above the market stress. We may conclude on the basis of Table 5 that there is a robust lead for the AOR over the CDS for banks which are relatively reliant on relationship lenders and (to some extent) for banks with below median size, on days of market stress. An (unreported) auxiliary regression shows that a low bank rating and small bank size are related to a high value for the bank's BPI index. These results are similar to those of Cocco et al. (2009) who find that "smaller banks and banks with more nonperforming loans tend to have limited access to international markets, and rely more on relationships". We also find that the BPI index is on average higher for banks in crisis countries. So, although it is understandable that reliance on relationship lenders together with market stress are the conditioning dummy-variables that best capture the relative informativeness of the bank's AOR (measured by the strength of the lead), there are more fundamental bank characteristics such as quality and size which in turn explain a bank's reliance on relationship lenders. As a robustness check, Table 6 reports largely similar results corresponding to those in Table 5 but using the conditioning variables as such in multiplicative interactive terms instead of first transforming them into dummy variables.

C. Economic significance of the results

Finally, we evaluate the economic significance of the lead coefficient for AOR over CDS. In general, we find that it depends on whether we consider short-term prediction of the CDS with the help of the AOR, or the long-term impact on the CDS of a permanent AOR shock.

Consider first the short-term perspective. Assume an increase of 30 bps in the AOR, which is roughly the estimated long-term change in the AOR corresponding to a 1000 bps change in the CDS; see Figure 2. Based on the basic VAR model from panel b) of Table 2, the estimated change in the next day's CDS would equal $0.0474 \times 30 \text{ bps} \approx 1.5 \text{ bps}$. This magnitude corresponds to the size of a bid-ask spread of a highly liquid bank CDS in our data. In any case, even for quite an extreme change in the CDS such as the one considered in this example, the additional contribution from the AOR would be very small in absolute terms. The economic significance of the lead would of course be higher for some banks, as the individual bank coefficients suggest in Table 4. Moreover, as results in Table 5 have shown, it would be stronger during market stress, especially for banks borrowing mainly from relationship lenders. In this case, according to the model in column (4) in Table 5, the effective lead coefficient would be approximately 0.13, implying that in the above example the estimated change in the next day's CDS would equal $0.13 \times 30 \text{ bps} \approx 3.9 \text{ bps}$.

Regarding the long-term, a stronger impact would follow if we used the level form specification for the CDS (Table 2a, left column) and considered a permanent change in the AOR. Due to the high persistence of the CDS, this model implies a fairly high long-term elasticity of 1.7 of the CDS with respect to a permanent change in the AOR. This

means that, e.g., a permanent 10 bp increase in the AOR would eventually increase the CDS by 17 bp.²⁶

To sum up, the economic significance of the lead of the AOR over the CDS probably remains modest in most circumstances. It is nevertheless useful to know on the basis of our results that the AOR can provide timely information regarding a bank's health, even more timely than the daily CDS price. To extrapolate this result, the AOR may provide quite useful information during market stress also of banks without a CDS.²⁷

IV. Conclusions

In this paper we have investigated the informativeness of banks' average overnight interbank borrowing rates over and above their CDS price. Because the overnight borrowing rates are privately negotiated between the borrower and the lender bank, they may reflect lenders' private signals concerning the borrower bank's financial health. In spite of their overnight maturity, these rates may become informationally sensitive during market stress. Because all private information may not be simultaneously reflected in the public CDS market, as a result of market frictions or possibly strategic reasons, it is possible that a bank's average overnight borrowing rate, which aggregates the private information signals, is more informative, at least in some periods, than the CDS price. To test this hypothesis we have used proprietary data on banks' overnight rates from the

²⁶ More specifically, the long-run impact on the CDS in the levels model is computed in the usual way, using the coefficients from Table 2a's left column as $(AOR_{t-1} + AOR_{t-2}) / (1 - CDS_{t-1} - CDS_{t-2})$. The very large size of the resulting long-run impact (which is around 15) reflects the large difference in the scales of the AOR and CDS variables. Therefore, to get a better grasp of the economic significance of the long-term impact, we also computed the corresponding long-term elasticity, resulting the value 1.7.

²⁷ This conjecture is further supported by the fact that banks which do not have a CDS are typically smaller than those banks which do, and by our result that the lead for AOR over CDS tends to be stronger for smaller banks.

Eurosystem's main large value payment system, TARGET2, over the period from mid-2008 to mid-2013.

We find that the daily changes of the average overnight rate spreads lead (in the sense of Granger causing) the respective CDS spreads for relatively weaker and smaller banks, for banks in crisis countries, for banks with a relatively illiquid CDS market, and for banks which are relatively reliant on relationship lenders. When these effects are allowed to control for one another, a robust lead exists for banks which are relatively reliant on relationship lenders and (to some extent) for banks with below median size, on days of market stress. These results are consistent with the general predictions from theories such as Dang et al. (2012). Our results may be informative to the authorities responsible for banks' stability in providing an additional source of short-term information for assessing the risk of financial crises and current state of the banking system.

Table 1
Descriptive statistics

This table reports the number of observations each year that are used in the regressions and the mean / standard deviation statistics for the key variables, AOR (EONIA subtracted) and CDS (iTraxx not subtracted), and the bank relationship variables: Herfindahl-Hirschman Index (HHI), Borrower Preference Index (BPI), and number of lenders of a bank (NL). For regressions involving stock price or credit rating the numbers of observations can be smaller than reported here due to lack of stock price information or credit rating for some dates. *Observations for year 2008 start at the beginning of June and for 2013 end at the end of June.

Year:	2008*	2009	2010	2011	2012	2013*	Total

Table 2
Basic lag-lead result for AOR and CDS

Panel a and b report the short-term results (difference of one and lag of one) of panel VAR for CDS (iTraxx subtracted) and AOR (EONIA subtracted). In parentheses are the standard errors. Panel c reports VAR where EONIA and iTraxx indices are not explicitly subtracted as well as a VAR for the indices alone. Panel d reports VAR for longer-time horizon, where the standard errors are adjusted for overlapping observations using the method of Bayley and Hammersley. (1946), see also Garrett and Petrie (1981) and Valkanov (2001). Superscripts ***, **, * indicate p-value less than 0.001, 0.01 and 0.05, respectively.

Table 3
Controls for robustness of the lag-lead relationship

This table reports the relevant coefficients from panel VAR regressions and results of Granger Causality tests for CDS (iTraxx subtracted), AOR (EONIA subtracted) and a set of control variables. Panel A reports the tests that a variable Granger causes CDS, Panel B reports similar results for causal sources for AOR, and Panel C for each of the control variables. We perform the VAR for each control variable separately. For example the VAR component for CDS reads $\Delta CDS_t = \beta_1 \Delta CDS_{t-1} + \beta_2 \Delta AOR_{t-1} + \beta_3 CTRL_{t-1} + \beta_0$ where *CTRL* is the control variable.

Table 4

Bank-level regression results

This table reports the relevant VAR coefficient and Granger causality test results when the VAR is done in the bank-level. The results for individual banks are ordered according to the smallest p value.

Table 5

Further characteristics of the lag-lead relationship

This table reports the results of panel VAR regressions for CDS (iTraxx subtracted), AOR (EONIA subtracted) and interactions of AOR with variety of dummy variables. In Panel A the dummy variable depends only on the day of the observation and not on the bank. In Panels B to D the panel the dummy categorizes observations each day according to the median of the variable relevant for that dummy that day. For example, if on 2010/05/14 the median CDS for observations is 144.00, then the "Higher CDS" dummy on that day is 1 for those banks whose CDS is above 144.00 that day. For the case of one dummy variable DUM, the relevant component of VAR equations is written as $\Delta CDS_t = \beta_1 \Delta CDS_{t-1} + \beta_2 \Delta AOR_{t-1} + \beta_3 \Delta AOR_{t-1} \times DUM_{t-1} + \beta_4 DUM_{t-1} + \beta_0$. Only the results related to this equation for CDS are shown. The constant coefficients β_0 and coefficients of CDS β_1 are all small and statistically insignificant and have been omitted for brevity. In all cases the R-sq is about 0.0010 and the number of observations is 46,729 (44,398 if credit rating is used). In parentheses are the standard errors. Superscripts ***, **, * indicate p-value less than 0.001, 0.01 and 0.05, respectively.

Table 6
Interactions

This table reports the relevant panel VAR coefficients and Granger causality tests that AOR and/or interaction term, which is a product of AOR and another variable, Granger causes CDS. We perform the VAR for each interaction term separately. The relevant VAR component reads $\Delta CDS_t = \beta_1 \Delta CDS_{t-1} + \beta_2 \Delta AOR_{t-1} + \beta_3 \Delta AOR_{t-1} \times VA_{t-1} + \beta_4 VA_{t-1} + \beta_0$ where VA is the other variable in the interaction term.

Interaction term	H0: AOR causes CDS			H0: Interaction term causes CDS		
	Coefficient x 1000	F-statistic	p-Value	Coefficient x 1000	F-statistic	p-Value
$\Delta AOR \times$ Rating	-103.063	59.901	0.000	25.378	175.425	0.000
$\Delta AOR \times$ BPI	47.902	30.696	0.000	-4.579	0.009	0.923
$\Delta AOR \times$ HHI	43.093	8.584	0.003	7.348	0.110	0.740

$\Delta AOR \times$ CDS bid-ask spread	46.811	42.055	0.000	0.011	0.083	0.773
$\Delta AOR \times$ AOR	49.485	50.343	0.000	47.601	5.685	0.017
$\Delta AOR \times$ CDS	-9.298	1.385	0.239	26.150	217.819	0.000

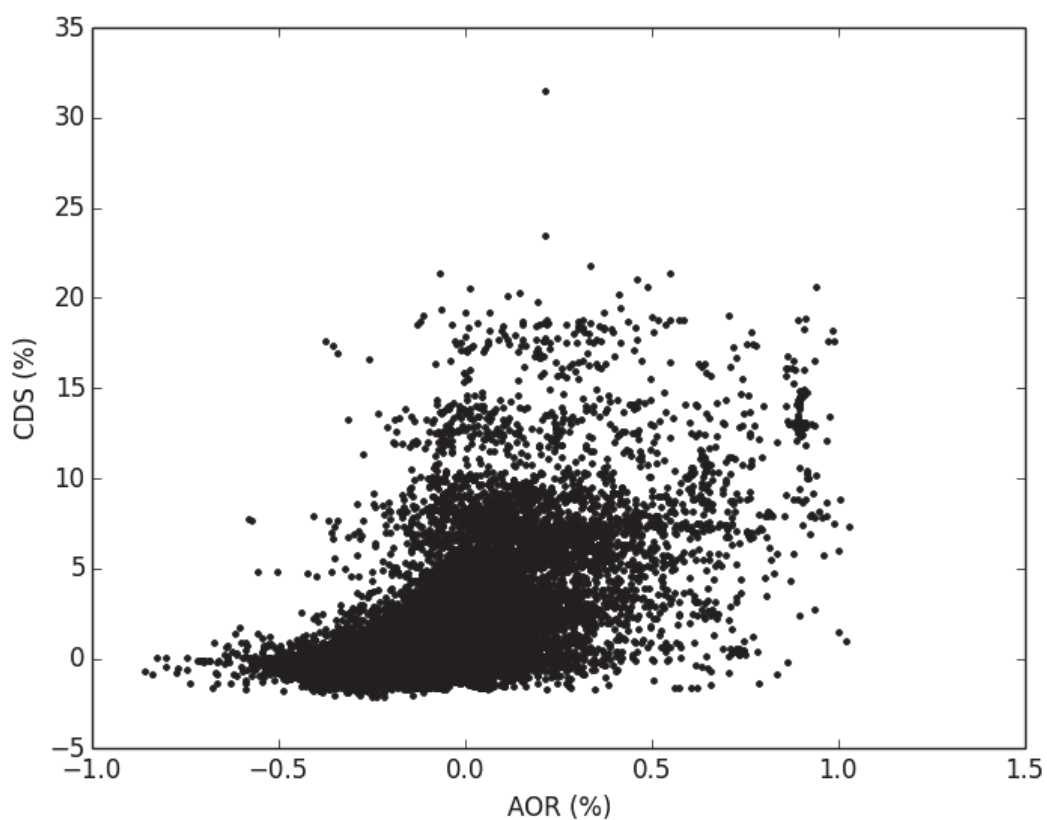

Figure 1. Scatter plot of the daily AOR and CDS observations. Each point corresponds to one of the 53,987 daily observations. A linear least square fit of the data reads $CDS = 7.79 (0.06) AOR + 1.54 (0.01)$ with standard errors in the parentheses and explained variance $R\text{-sq} = 0.26$.

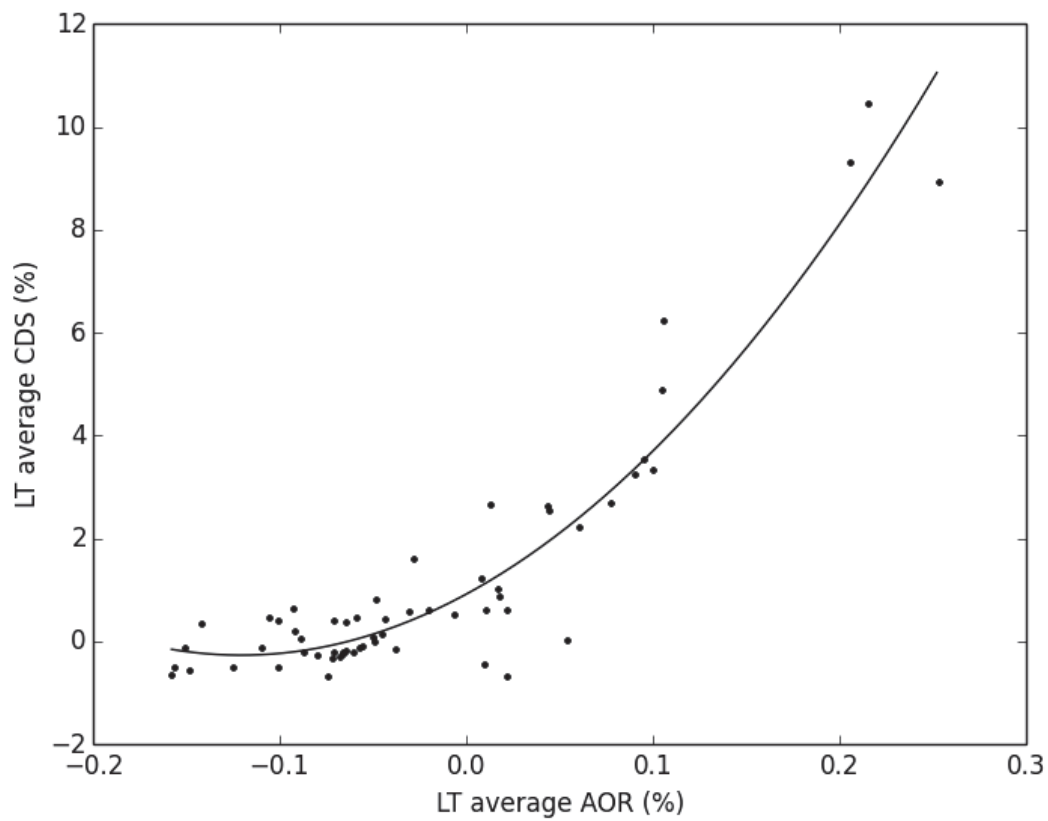

Figure 2. Long-term average of AOR and CDS. Each point corresponds to one of the 60 banks and the data is averaged over the whole period from begin of June 2008 to end of June 2013. The parabola is an OLS fit with equation $CDS = 19.56 (1.26) AOR + 81.30 (9.52) AOR^2 + 0.93 (0.14)$ with standard errors in the parentheses and the explanatory power (R-squared) equal to 0.89.

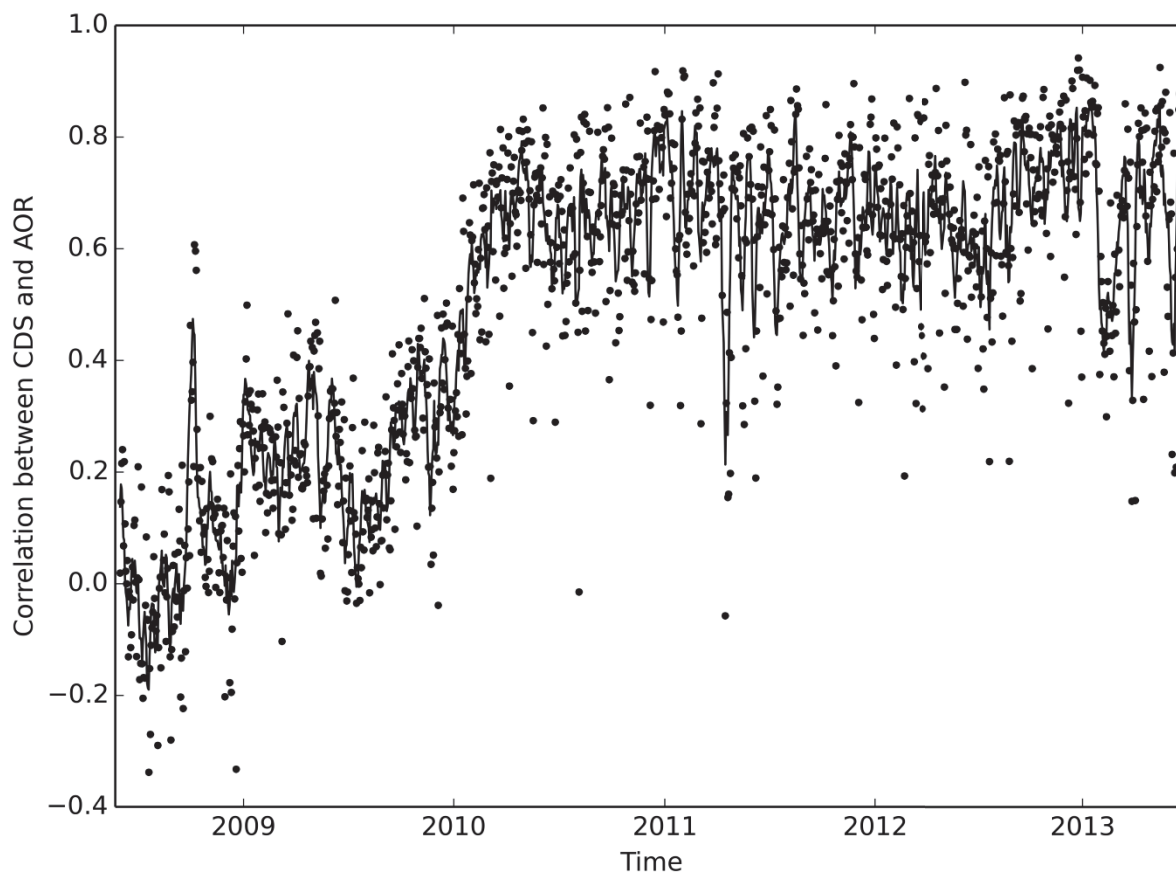

Figure 3. The cross-sectional correlation between CDS and AOR. The dots are the daily cross-sectional correlation values. For illustrational purposes the line shows 5 day moving average. The correlation is calculated across those of the 60 panel banks that participate in the money market in the corresponding business day. The short-term variation of the correlation is thus partially attributed to different sample in different days.

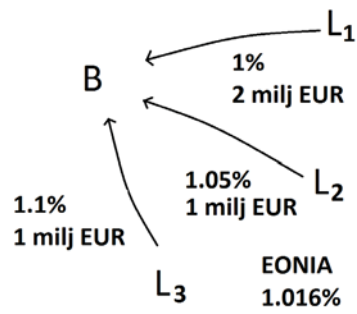

Figure 4. Illustration of how the Average Overnight Rate (AOR) is calculated. We apply uniform weights and subtract the EONIA so that the resulting AOR is $(1\%+1.05\%+1.1\%)/3-1.016\% = 0.034\%$.

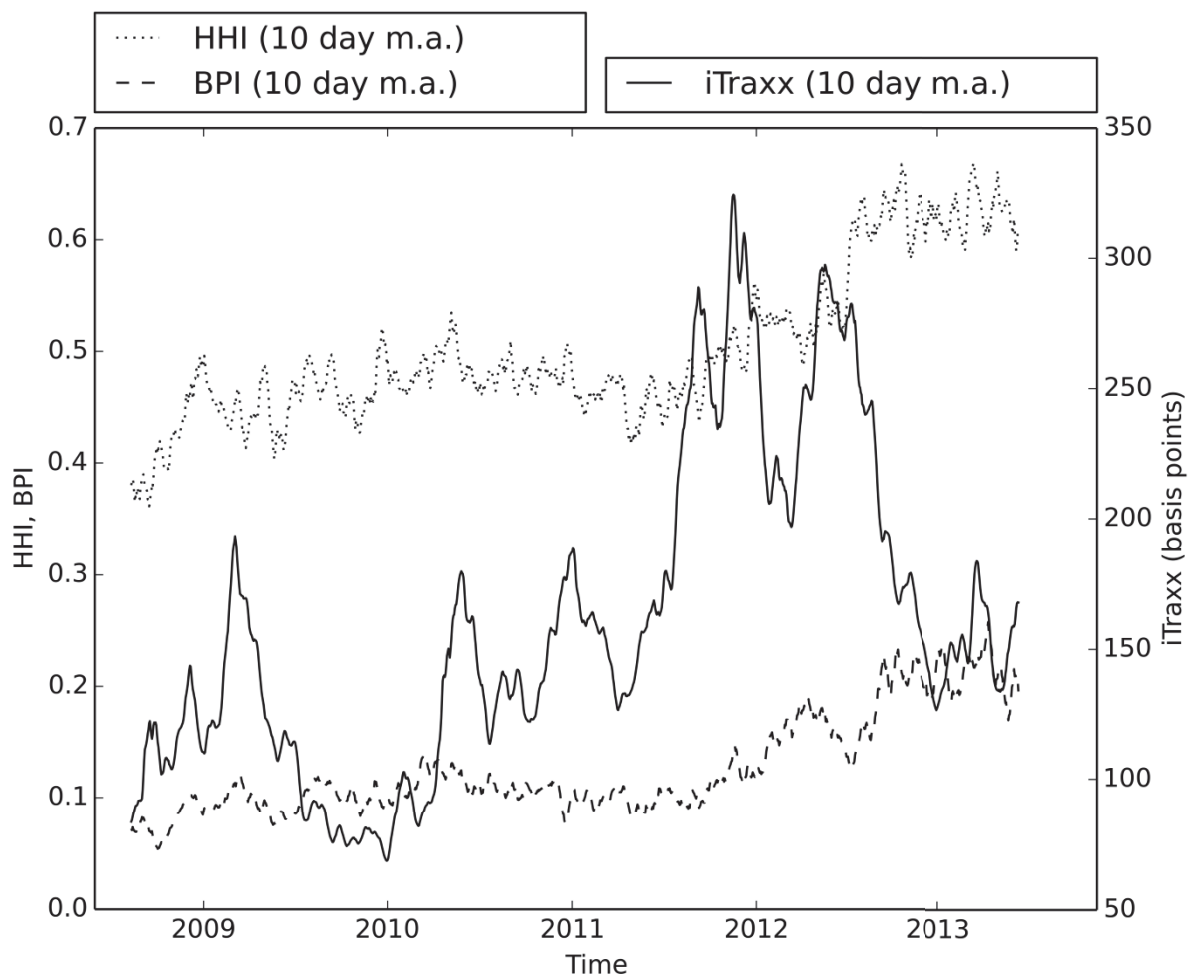

Figure 5. Average Herfindahl-Hirschmann Index (HHI), average Borrower Preference Index (BPI) and iTraxx Europe Financial subindex. HHI and BPI are calculated as average HHI or BPI of the observations in our panel for each day. Not all 60 banks participate in the market each day. For ease of illustration, 10 day moving average is shown. Daily values (not moving average) are used for calculation of the correlations below. The correlation between HHI and BPI is 0.78. With effect from 11th July 2012, the ECB Deposit facility rate has been 0.00 % and the HHI and BPI indices show more concentrated borrowing due to change in the incentives of market participants. If this latter period is left out, the correlation between BPI (HHI) and iTraxx is 0.44 (0.43) otherwise 0.29 (0.34).

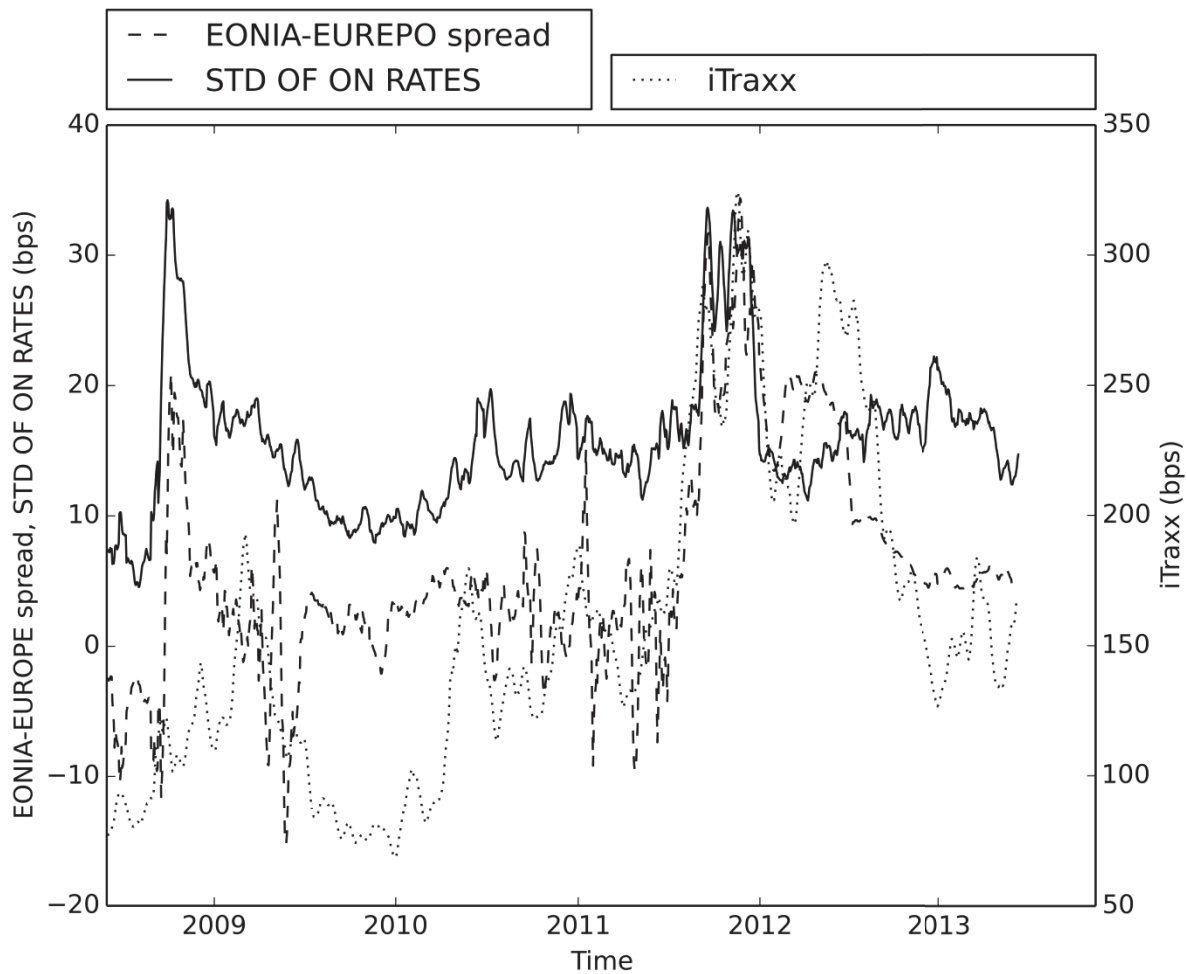

Figure 6. EONIA-EUREPO spread (EONIA-EUREPO), Standard deviation of overnight rates (SD) and iTraxx Europe Financial index. EONIA-EUREPO spread is the spread between uncollateralized and collateralized overnight loans. Standard deviation of overnight rates is calculated daily from the all the observed overnight loans (not restricted to the 60 banks). For illustrational purposes, 10 day moving average is shown. Daily values (not moving average) are used for calculation below. A linear regression of iTraxx on the rate data gives $iTraxx = 302.401 (14.18) EONIA-EUREPO + 264.41 (23.50) SD + 98.37 (3.67)$ with standard errors in the parentheses and the explained variance of regression $R-sq = 0.42$.

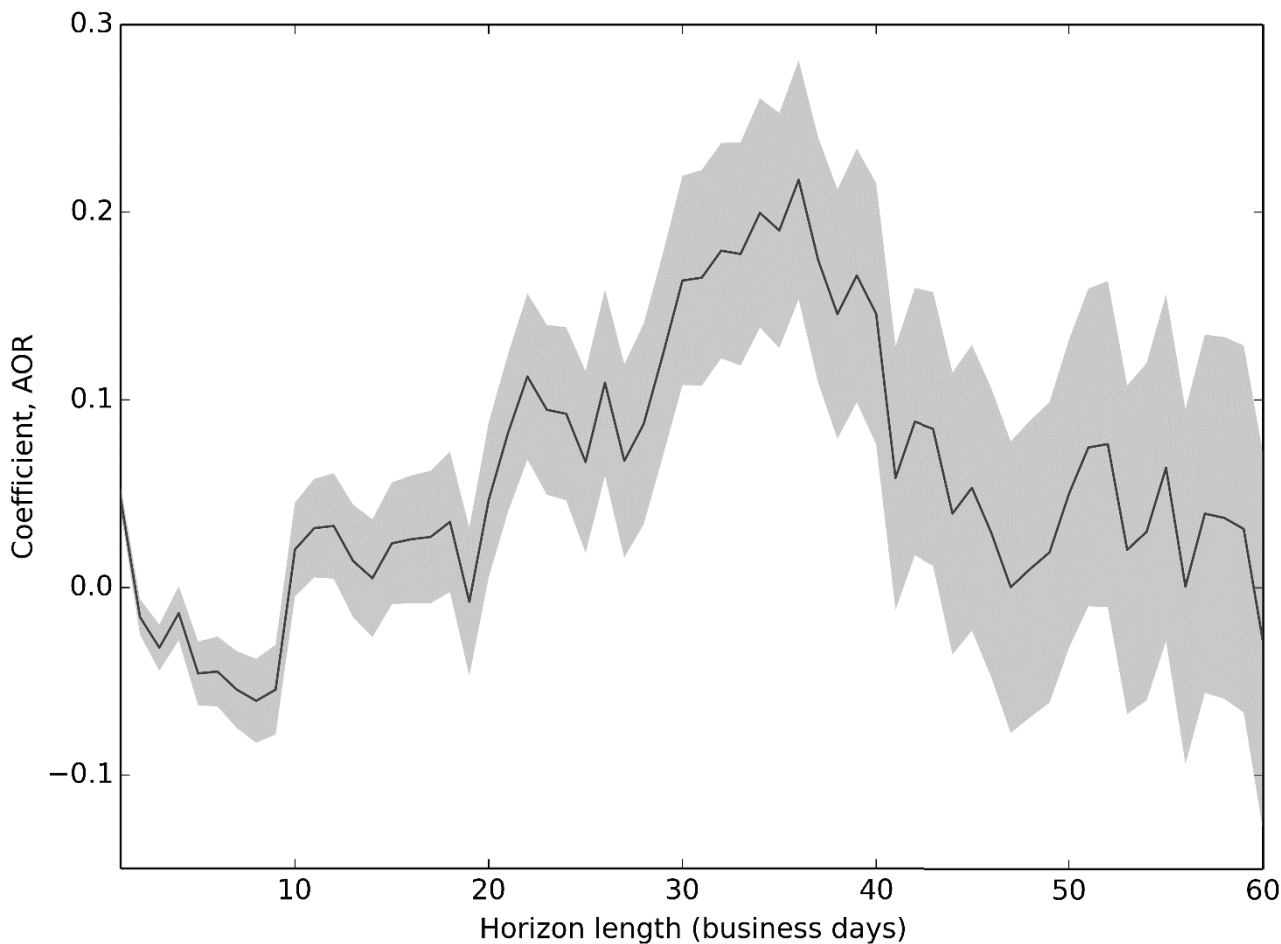

Figure 7. Coefficient of lagged CDS for different horizon lengths in the long-term VAR, which corresponds to β_1 in the equation $\Delta_h CDS_t = \beta_1 \Delta_h AOR_{t-h} + \beta_2 \Delta_h CDS_{t-h} + \beta_0$, where h is the horizon length. Shaded area show the standard error adjusted for overlapping observations using the method of Bayley and Hammersley, 1946, see also Garrett and Petrie 1981.

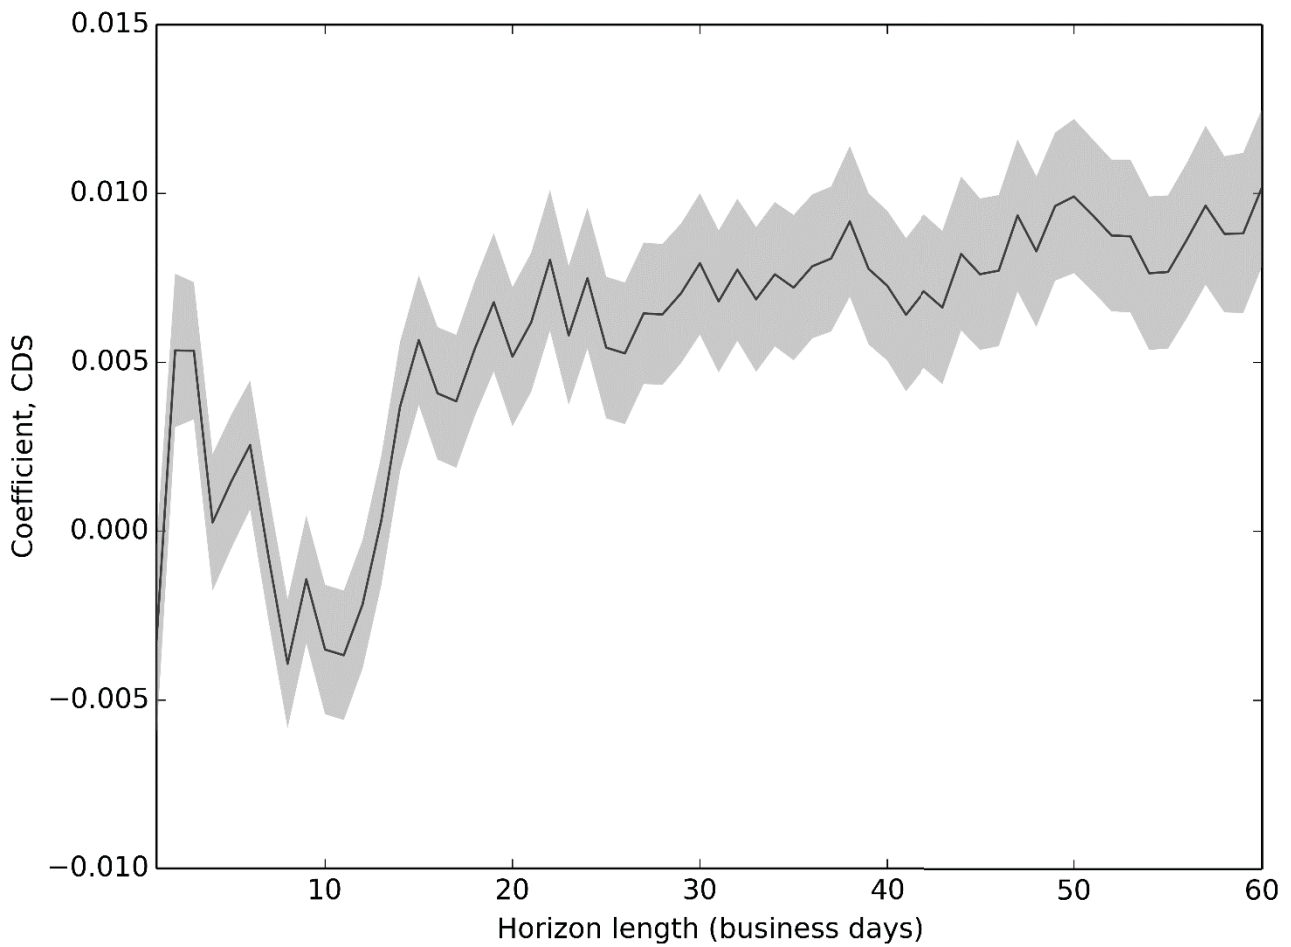

Figure 8. Coefficient of lagged CDS for different horizon lengths in the long-term VAR, which corresponds to β_2 in the equation $\Delta_h AOR_t = \beta_1 \Delta_h AOR_{t-h} + \beta_2 \Delta_h CDS_{t-h} + \beta_0$, where h is the horizon length. Shaded area show the standard error adjusted for overlapping observations using the method of Bayley and Hammersley, 1946, see also Garrett and Petrie 1981.

Acknowledgements

We thank an anonymous referee, Simone Giansante, Iftekhar Hasan, Ian Marsh, Niko Herrala, Jouko Vilmunen, Tuomas Välimäki, and seminar and workshop participants at the Bank of Finland, Deutsche Bundesbank, and Universitat Pompeu Fabra for valuable comments. All remaining errors are ours. Eero Tölö is a member/alternate of one of the user groups with access to TARGET2 data in accordance with Article 1(2) of Decision ECB/2010/9 of 29 July 2010 on access to and use of certain TARGET2 data. The Bank of Finland and the PSSC have checked the paper against the rules for guaranteeing the confidentiality of transaction-level data imposed by the PSSC pursuant to Article 1(4) of the above mentioned issue.
